ACKNOWLEDGEMENTS

The authors wish to thank Sustainable Resource Development Staff including:

Keith Ainsley for helpful editing comments and suggestions for the vegetation sections of the report and

Michelle Richard, also with Sustainable Resource Development, for her word processing assistance in the report preparation.

The authors would also like to thank the Alberta Peat Task Force for their financial, technical, and scientific support of the inventory program that enabled us to refine out wetland classification concepts. Additional funding was provided by the Sustainable Forest Management Network, Centres of Excellence.

1.0 INTRODUCTION

This report represents a supplemental update to the Alberta Wetland Inventory (AWI) Standards Version 1.0 that was developed by Vitt *et al.* (1996). While the classification system remains the same as the initial version, this report provides additional information that will allow for:

- Verification of wetland type identified from aerial photography by field-based investigations conducted as part of the Alberta Peat Task Force (Appendix 1, 2, and 3)
- Alignment of ecosite phase classification of Beckingham and Archibald (1996) with AWI
- Recommended coding form (Appendix 4)

The classification scheme used for this report follows the classes developed by the National Wetlands Working Group (1988), with subclasses recognized on the basis of vegetation and landform type at both the wetland complex and more local wetland element level. The Alberta Wetland Inventory Classification contains four levels that include 1) wetland class (National Wetlands Working Group 1988); 2) vegetation modifier; 3) wetland complex landform modifier; and 4) local landform/vegetation modifier. Of the possible combinations that can occur, 15 wetland types are common in Alberta (Vitt *et al.* 1996), though other wetland types can and do occur.

As AWI is based on gross characteristics of vegetation visible from aerial photographs, the general structure of vegetation is different between AWI types (Vitt *et al.* 1996). However, the details of plant communities that make up this general vegetation can vary within an AWI class (Forest 2001). For each wetland type the architecture of how vegetation is structured vertically (layers) and spatially (microhabitats) will differ. Common plant species and community architecture will be discussed for each of the fifteen common wetland types. In addition, 106 sites examined for plant composition, layer, and microhabitat structure as part of the Alberta Peat Task Force (Appendices 1, 2, and 3) will be analysed by wetland type using canonical correspondence analyses (PCORD 1999). The objective of this exercise is to examine how vegetation and community structure compare and contrast within and between wetland types to aid users in field verification of AWI interpretation.

2.0 DEFINITION OF WETLANDS AND WETLAND CLASSES

In Canada wetlands have been defined as "...land that is saturated with water long enough to promote wetland or aquatic processes as indicated by poorly drained soils, hydrophytic vegetation and various kinds of biological activity which are adapted to a wet environment" (National Wetlands Working Group 1988). The environmental processes that control wetland development form hydrologic, chemical, and biotic gradients and commonly have strong cross-correlations. These interrelated gradients are here divided into five nodes that define wetland classes used in this report, of which two are peatlands with > 40 cm of accumulated organics and three are non-peat forming wetlands generally having < 40 cm of accumulated organics. Peatlands are subdivided into 1) fen and 2) bog; whereas non-peat forming wetlands are subdivided as 1) shallow open water, 2) marsh, and 3) swamp (Figure 1). This primary wetland subdivision forms the foundation for defining Alberta wetlands and has been recognized by the Provincial Government within draft policy (Alberta Water Resources Commission 1993).

Peatlands differ from non-peat forming wetlands by a combination of interrelated hydrologic, chemical, and biotic factors that results in a decrease in decomposition relative to plant production allowing for the accumulation of peat. The stabilization of seasonal water levels and restriction of water flow through a wetland allows for the establishment and development of a bryophyte layer. The stabilization of regional water tables appears to have been an important component in the successional change from prairie marshes to boreal fens in the western interior of Canada over the past 10,000 years (Zoltai and Vitt 1990).

The establishment of a bryophyte layer results in the accumulation and maintenance of nutrients in a nonavailable form, reducing vascular plant production. Stabilized water levels, anaerobic conditions, and decreased nutrient availability lead to a substantial decrease in decomposition rates, that results in the development of peat accumulating ecosystems (Vitt and Kuhry 1992). Biotic (*Sphagnum* presence) and chemical (decomposition) processes lead to acidification and oligotrophication. Alberta peatlands are classified into geogenous fens and ombrogenous bogs, each with distinctive indicator species, acidity, alkalinity, and base cation content (Figure 1).

FIGURE 1. Ternary diagram of wetland classes and their relationship to chemical and biotic gradients
(Modified from Vitt 1994).

Fens are geogenous ecosystems that are affected by mineral soil waters (ground and/or surface) that may be relatively rich in mineral elements. Fens can be subdivided on the basis of hydrology into: soligenous and largely influenced by flowing surface water; topogenous and largely influenced by stagnant ground water; or limnogeneous and largely influenced by associated lakes and ponds. All three fen types have water levels at or near the peat surface. Soligenous fens commonly have discrete patterns of open pools (flarks) alternating with elongate, shrubby to wooded ridges (strings) oriented perpendicular to the direction of surface water flow. These patterned fens may be either acidic or basic. Topogenous, limnogenous, and some soligenous fens are nonpatterned. Fens can be open and dominated by *Carex*, *Scirpus*, and *Eriophorum*; shrubby and dominated by *Betula* and *Salix*; or wooded to forested dominated by some combination of *Picea mariana*, *Larix laricina*, *Betula*, and *Salix*.

Originally based on criteria derived from vegetation, fens have in the past been subdivided on the basis of the number of indicator species. Poor fens are low in indicator species, while extreme-rich fens are high in indicator species; moderate-rich fens are intermediate. This gradient of indicator species correlates with a chemical gradient (Sjörs 1952). Poor fens are acid (pH 4.5-5.5), poor in base cations and have no or little alkalinity. They are dominated by oligotrophic and mesotrophic species of *Sphagnum*. Moderate-rich fens have slightly acid to neutral pH (5.5-7.0) and have low to moderate alkalinity with a ground layer of brown mosses namely: *Drepanocladus*, *Brachythecium*, *Calliergonella*, and low abundances of mesotrophic species of *Sphagnum*. Extreme-rich fens have basic pH (above 7.0), high concentrations of base cations, and high alkalinity. They are characterized by species of *Drepanocladus*, *Scorpidium*, and *Campylium* and may contain marl deposits.

Bogs are ombrogenous peatlands that receive their water only from precipitation and have low water flow. The water table is generally 40-60 cm below the peat surface. For these reasons bogs are acidic ecosystems with pH below 4.5; they are poor in base cations, and have no alkalinity. Bogs are dominated by oligotrophic species of *Sphagnum*; feather mosses: *Pleurozium schreberi* and *Hylocomium splendens*; and lichens of *Cladonia* and *Cladina*. They may be open, wooded or forested with trees limited to *Picea mariana*. As a result of the low thermal conductivity of dry *Sphagnum*, bogs have lower surface water temperatures than other surrounding organic and nonorganic soils. Regional permafrost is

consequently restricted to bogs at its southern limit, where it forms peat plateaus and palsas (Vitt et al. 1994).

Marshes are open, non-peat forming wetlands that are dominated by sedges (Cyperaceae) and other monocots. Marshes are characterized by seasonal water level fluctuations, relatively high amounts of water flow, and are influenced by ground and surface waters. As a result, concentrations of nitrogen and phosphorus are high, leading to abundant vascular plant production; however, peat accumulation is limited by high decomposition rates. Bryophytes are generally lacking or not abundant as they do not compete well with rapid vascular plant growth and do not tolerate large fluctuations in seasonal water levels. As with shallow open waters, chemical differences in marshes strongly influence their floristic composition. Alkaline marshes (dominated by calcium and bicarbonate) are dominated by *Carex*, *Scirpus*, and *Typha* whereas saline marshes (dominated by sodium and sulfate) are largely occupied by *Salicornia* and *Scirpus*.

Swamps are forested, wooded or shrubby non-peaty wetlands. Swamps and marshes have a poorly developed bryophyte layer that results from strong seasonal water level fluctuations and high vascular plant production. Peat accumulation is limited in swamps as decomposition rates are high. Vegetatively swamps are quite diverse and in Alberta may be composed of some combination of *Larix laricina*, *Picea mariana*, *Betula*, and *Salix*. Swamps can have a poor- to well-developed bryophyte layer but, different from peatlands, always have substantial areas of microhabitats that completely lack or have few bryophytes.

Shallow Open Waters are non-peat forming wetlands that are characterized by aquatic processes confined to less than 2 m depth at midsummer. These wetlands have submergent to floating vegetation and form a transition to truly aquatic ecosystems, and may represent more permanent ecosystems, or transitory system generated by flooding of land. The chemistry of this wetland class is variable and does not distinguish it from the remaining four wetland classes, and floristic composition is dependent on chemical conditions.

3.0 SUBDIVISION OF WETLAND CLASSES

Wetland types (bogs, fens swamps, marshes, and shallow open waters) are further subdivided into three subclasses on the basis of vegetation and landform criteria at the wetland complex and more local wetland element scale (Table 1). The second subdivision of AWI is a forest cover classification, with three possible levels-forested >70% tree cover; wooded >6 to \leq 70% tree cover; and open \leq 6% tree cover. By definition not all five classes can be placed into all three subdivisions. While bogs, fens, and swamps may be forested, wooded, or open; marshes and shallow open waters may only be open as wooded to forested non-peat accumulating wetlands are always classified as swamps.

The third subdivision of AWI is a wetland complex landform modifier that recognizes the presence of patterning and permafrost (Table 1). In Alberta patterning is restricted to fens, whereas regional permafrost is almost exclusively restricted to bogs. For this reason all non-peat accumulating wetlands will always have a third subdivision classification of N. Bogs may be X or N but never P, and fens may be P or N but never X.

The fourth subdivision of AWI is a local wetland element landform or vegetation modifier (Table 1). Open wetlands may be given a subclass modifier recognizing shrubby or graminoid vegetation, while forested to wooded peatland classes may receive permafrost related local modifiers of C, R, I, or N. Wooded to forested non-peat accumulating wetlands are restricted to a fourth subdivision modifier of N as local permafrost is almost exclusively restricted to peatlands in Alberta.

While vegetation of individual wetland types can be similar (Forest 2000), the architecture of how various plant communities and microhabitats are spatially structured across the wetland landscape differs between each wetland type. Hence, different wetland types identified from aerial photography have characteristic vegetative architecture that can be utilized to verify wetland types interpreted from aerial photos.

TABLE 1: Wetland classification scheme

WETLAND CLASS	Bog	B
	Fen	F
	Swamp	S
	Marsh	M
	Shallow Open Water	W
	Non-wetland	Z
VEGETATION MODIFIER	Forested: closed canopy >70% tree coverage	F
	Wooded: open canopy >6-70% tree coverage	T
	Open: shrubs, sedges, graminoids, herbs, etc. \leq 6% tree cover	O
WETLAND COMPLEX LANDFORM MODIFIER	Permafrost is present	X
	Patterning is present	P
	Permafrost or patterning is not present	N
LOCAL LANDFORM MODIFIER	Collapse scar	C
	Internal lawn with islands of forested peat plateau	R
	Internal lawns	I
	No internal lawns are present	N
	Shrub cover > 25% when tree cover \leq 6%	S
	Graminoid dominated with shrub cover \leq 25% and tree cover \leq 6%	G

4.0 WETLAND ARCHITECTURE: VEGETATION LAYERS AND MICROHABITATS

Wetland architecture is here defined as the characteristic physiognomy (vegetation layer organization) and microhabitats present in a wetland. Vegetation layers are the vertical structure present within a wetland type, while microhabitats represent an environment that has a unique set of ecological conditions within a wetland.

Wetland sites examined as part of the Alberta Peat Task Force were evaluated for vegetation cover in relation to the architectural distribution of each layer and microhabitat present (Appendix 2 and 3). Vegetation layers were subdivided vertically into the overstory, understory, and groundcover with further subdivision in each based on vertical height and vegetation type. The overstory was subdivided into four sublayers that included 1) tree cover > 10m; 2) tree/shrub cover of 2 – 10m; 3) tree/shrub cover of 0.5 to 2m; and 4) tree/shrub cover of <0.5m. The understory was subdivided into herb and graminoid cover while the ground layer was subdivided into seven components: 1) bryophytes; 2) lichens; 3) bare peat (no living vegetation present); 4) coarse woody debris; 5) rocks; 6) aquatic vascular plants; and 7) open water. In addition, the number of snags were counted.

In contrast, wetland microhabitats were structured into substrate type and relative position to the water table. Nineteen wetland microhabitats were recognized that included ten associated with specific substrates: 1) tree stumps; 2) tree trunks; 3) tree bases; 4) logs; 5) shrub bases; 6) grass tussocks; 7) dung/skeletons; 8) small lawns (small uniform area with little microtopography); 9) root mounds; and 10) bare peat (apparently non-living ground cover). An additional nine microhabitats were recognized along a moisture gradient that included from driest to wettest: 11) peat plateau surface (elevated peat surface underlain by permafrost); 12) string (linear raised area trending perpendicular to surface water flow); 13) hummocks (top of elevated mound); 14) hummock sides (side of elevated mound); 15) hollows (intervening areas between hummocks above water table); 16) lawns (large uniform area with little microtopography); 17) carpets (uniform area with water table closer to the peat surface than in lawn areas, peat is often a floating mat); 18) wet holes (small <50 cm diameter, deep depressions that extend below the water table); and 19) pools (large > 50 cm diameter, deep depressions that extend below the water table).

Not all wetland types will have all vegetation layers and microhabitats. However, some wetland types will have a distinctive suite or affinity for certain layers and microhabitats. Distinctness and/or preference of different wetland types for these architectural elements are evident in a Canonical Correspondence Analyses (CCA) of wetland vegetation (Figures 2 and 3). Several of the different wetland types identified from aerial photo interpretation cluster into regions of the CCA, though overlap between some types does occur. As the CCA ordinales sites along layer or microhabitat variation, wetland type location on the CCA reflects preference for those layers and microhabitats, while the degree of isolation marks the degree of distinctness.

FIGURE 2: Canonical correspondence analysis of plant community data from 105 wetland sites by layer examined as part of the Alberta Peat Task Force (Appendix 2 and 3). Location of each layer is shown on the CCA with individual wetland sites designated by type with symbols. The AWI class of each site is shown by symbols. Sites have affinities for layers they are closest to on the ordination. Distribution of sites on the first two axes represents 49.7% of the variance in the data set.

FIGURE 3: Canonical correspondence analysis of plant community data from 105 wetland sites by microhabitat examined as part of the Alberta Peat Task Force. Location of each microhabitat is shown on the CCA with individual wetland sites designated by type with symbols. Sites have affinities for microhabitats they are closest to the on the ordination. Distribution of sites on the first two axes represents 49.7% of the variance in the data set.

5.0 LINKAGE OF AERIAL PHOTOGRAPH INTERPRETATION AND FIELD BASED STUDIES

Bogs

Bogs develop in areas of restricted surface water flow and are found along drainage divides, in stagnation zones of peatland complexes created in the lee of surface water flow obstructions, and in small, isolated basins. Bogs are subdivided into forms based on forest cover, with open bogs having $\leq 6\%$ cover (excluding areas that have recently burned), wooded bogs having > 6 to 70% cover, and forested bogs having $>70\%$ cover. In continental western Canada, bogs are forested exclusively with *Picea mariana* (Vitt et al. 1994). The presence of permafrost and internal lawns is also used in subdividing bogs following Vitt et al. (1994). Following these criteria, five bog forms can be recognized in Alberta.

Veneer bogs with or without collapse scars (**Boxc** and **Boxn**)

Aerial Photo Interpretation

Veneer bogs are characterized by a thin layer of peat generally $0.4 - 1.5$ m. They contain permafrost and overlie gently sloping terrain. Veneer bogs have a scanty tree cover (generally $\leq 6\%$) and may contain circular to irregularly shaped collapse scars that have a sharp boundary with the surrounding bog. On aerial photographs, veneer bogs are recognized by a light tone and a rough texture generated by the high reflectance of patchy lichen ground cover (Figure 4). They can be associated with circular collapse scars that have an even lighter and brighter tone. Unlike other peatlands in Alberta, veneer bogs may be found on low angle slopes grading into wooded, permafrost dominated bogs (peat plateaus) in areas where the surface expression is level. When found on low angle slopes, veneer bogs are associated with medium toned, parallel runnels oriented downslope representing drainage areas that are wooded with *Picea mariana* and *Larix laricina* (Figure 5).

Vegetation

Ground cover on the veneer bog is dominated by feathermosses such as *Hylocomium splendens* and *Pleurozium schreberi*, interspersed with hummocks of *Sphagnum fuscum*. Lichens of *Cladonia*, *Cetraria*, and *Cladina* are also common. Collapse scars are located approximately 100 cm below the bog surface and have a ground cover dominated by *Carex* and wet species of *Sphagnum*. While topography

associated with runnels and interrunnel areas can be poorly expressed, changes in tree density and height (denser and taller within runnels) allows for their recognition on the ground, in addition to the presence of other species not typically found within bogs (i.e. *Betula papyrifera*, *Cornus canadensis*, and *Frageria vesca* (Zoltai et al. 1988)). No sites examined as part of the Alberta Peat Task Force were located within veneer bogs, as they are generally restricted in occurrence to Alberta's northernmost uplands (Vitt et al. 1996). Though the vegetation of veneer bogs is not different from other bog types, particularly other permafrost bog types, the occurrence of this wetland on slopes and the characteristic architecture of runnel and interrunnel areas is unique to wetlands within continental western Canada.

Wooded to forested permafrost bogs (peat plateaus) with or without collapse scars (**Btxc**, **Bfxc**, **Btxn**, and **Bfxn**)

Aerial Photo Interpretation

Wooded to forested permafrost bogs are wetlands that contain perennially frozen peats. As such, wooded to forested permafrost bogs are similar to veneer bogs, however unlike veneer bogs they only occur on level surfaces. They have a relatively flat, raised surface, that is elevated above the surrounding wetland by 1 – 2 m, and can vary from small, isolated islands within larger wetland complexes, or as complex networks of large, coalescing plateaus within a discontinuous, interconnected matrix of nonpermafrost fen. Tree heights on wooded to forested permafrost bogs are generally more uniform than on veneer bogs as the lack of runnels does not promote increased tree growth. In addition, as the name implies wooded to forested permafrost bogs can support a higher density of tree growth. Aerial photo recognition of wooded to forested permafrost bogs is based on a dark tone, and a smooth, "velvety" texture (Figure 6). Small, circular, light toned areas (representing collapse scars) within a matrix of *Picea mariana* forest are diagnostic of this wetland form (Figure 7). Unlike other wooded bog wetland forms, wooded to forested permafrost bogs can have margins with acute angles while nonpermafrost bogs tend to have rounded margins.

Vegetation

Wooded to forested permafrost bogs are found in increasing frequency north of the Lower Foothills and the southern extension of the Dry Mixedwood Subregion (Vitt et al. 1994). They are typically more

heavily forested at the southern limit of their occurrence within the Central Mixedwood Subregion, with crown closure decreasing as mean annual temperature decreases. The amount of bare surface peat (apparently non-living ground cover) increases as crown closure increases, with presence of bare peat one of the ubiquitous microhabitats. While vegetation can be similar between permafrost and nonpermafrost bogs on the bog proper (Belland and Vitt 1995), permafrost bogs tend to have a greater proportion of bare peat and higher lichen cover (Belland and Vitt 1995). Differences in microhabitat distribution and associated vegetative differences between permafrost and nonpermafrost bogs are a function of the relative position of the water table (57 ± 24 cm and 35 ± 15 cm below the surface for permafrost and nonpermafrost bogs respectively [Appendix 2]), in addition to shade (Belland and Vitt 1995). As mentioned above, permafrost bogs are more heavily wooded at their southern limit (Central Mixed Wood Subregion), with dense tree cover associated with tall *Picea mariana*. Here, the close association of dense forest cover and bare peat is evident as frequent squirrel middens and/or dense coniferous litter.

Data collected as part of the Alberta Peat Task Force (Appendix 2 and 3) show permafrost bogs have a cover of 20% and 60% for >10 m and 2 – 10 m tree heights respectively. In comparison, nonpermafrost bogs had a mean cover of 0.2% and 28% for >10 m and 2 – 10 m tree heights respectively. The distinctness of wooded permafrost bog wetland types can be seen by their separation in a CCA diagram of wetland type and vegetation layers, where wooded permafrost bog sites (BTXC) are isolated from all other wetland types (Figure 2). Isolation is a function of not only low water table but also of high cover values for tall tree (> 10 m) and bare peat surfaces.

As with other bog types, tree cover on wooded permafrost bogs are almost exclusively restricted to *Picea mariana*, though *Betula papyrifera* can be present, and commonly establishes after fire. Vascular plant species composition and structure are also similar to other bogs types. The shrub layer is dominated by *Ledum groenlandicum*, with lesser numbers of *Alnus rugosa*, *Chamaedaphne calyculata*, *Kalmia polifolia*, *Rubus chamaemorus*, and occasional clumps of *Salix* spp. The herb layer commonly includes *Carex* spp., *Eriophorum* spp., *Smilacina trifolia*, and *Vaccinium vitis-idaea*. Ground cover in permafrost bogs is

dominated by lichens (mostly species of *Cladina*, *Cetraria* and *Cladonia*), and can be interspersed with *Pleurozium schreberi*, *Sphagnum fuscum*, and *Polytrichum strictum* along the peat plateau surface.

Wooded to forested, permafrost bog collapse scars are typically 100 cm lower than the surrounding bog surface and may be present as isolated, circular areas or as interconnected, elongate drainage channels. Vegetation within collapse scars is dominated by *Carex* spp. and a general lack of tree and shrub cover (Figure 8) with an extensive groundcover layer that is almost exclusively *Sphagnum*, with species including *Sphagnum angustifolium*, *S. jensenii*, *S. majus*, *S. obtusum*, and *S. riparium*. Often collapse scars have dead, dying, or leaning trees present on one or more sides, typifying the concept of “drunken forest” (Figure 8). Wooded to forested, permafrost bogs with collapse scars are often referred to as peat plateaus with collapse scars (Zoltai 1971, National Wetlands Working Group 1988). The presence of collapse scars and associated microhabitats (carpets and lawns) shift the location of this wetland type on the microhabitat ordination (Figure 3), hence for microhabitat cover wooded permafrost bogs are not isolated from other forested wetland types.

Wooded bogs without internal lawns (Btnn)

Aerial photo interpretation

Wooded bogs without internal lawns have a flat, homogenous surface that is uniformly wooded. Bogs without internal lawns occur as islands within large complex fens or as peninsulas protruding into large fens. Bogs can also be found confined to small basins associated with hummocky terrain or in broad, poorly defined depressions as well as along drainage divides. On aerial photographs, wooded bogs without internal lawns are recognized by a medium to dark tone and a smooth, “velvety” texture (Figure 9). There is no evidence of surface water movement as there is in wooded fens and unlike coniferous swamps, they are not found in areas of fluctuating water levels such as along stream courses, though they may occur adjacent to small isolated, circular to scallop-shaped lakes (Figure 9). Wooded bogs are distinguished from stands of *Picea mariana* occurring on uplands by their smooth, level surface, and relatively low tree height. Unlike wooded permafrost bogs, they contain only seasonal ice, are only elevated from surrounding fens by 40 cm, and do not contain collapse scars.

Vegetation

As with permafrost bogs, nonpermafrost bogs have a characteristic landscape architecture that is dominated by hummocks and hollows in addition to microhabitats associated with trees (fallen logs, tree bases, snags etc.). Carpets and lawns, that are typical of collapse scars and internal lawns are not present in nonpermafrost bogs without internal lawns. The distinctive architecture of wooded nonpermafrost bogs without internal lawns is reflected in its separation from other wetland types in both the layer (Figure 2) and microhabitat (Figure 3) ordinations, where only wooded nonpermafrost fen overlap slightly.

Nonpermafrost bogs without internal lawns have a tree cover that is almost exclusively restricted to *Picea mariana* (Figure 10). Vascular plant species are also similar to other bogs types. The shrub layer is dominated by *Ledum groenlandicum*, with lower numbers of *Chamaedaphne calyculata*, *Kalmia polifolia*, and *Rubus chamaemorus*. Unlike permafrost bogs, shrubs of *Alnus rugosa* and *Salix* spp. and *Carex* spp. are virtually absent. *Eriophorum* spp., *Drosera* spp. and *Smilacina trifolia* as well as the shrubs *Vaccinium oxycoccus* and *V. vitis-idaea* are common. Ground cover in nonpermafrost bogs is dominated by *Sphagnum*: *S. fuscum*, *S. magellanicum*, and *S. angustifolium*, brown mosses (*Aulacomnium palustre*, *Dicranum* spp. and *Mylia anomala*) feather mosses (*Hylocomium splendens*, *Pleurozium schreberi*, and *Ptilium crista-castrensis*) and lichens (mostly species of *Cladina*, *Cetraria* and *Cladonia*), within a hummock and hollow architecture. The dominance of *Sphagnum* cover and lower amounts of lichens and other mosses is reflected in the separation of this wetland type in the CCA ordination diagram from permafrost bogs as well as wetter wooded fens (Figure 3).

Wooded bogs with forested permafrost bog and internal lawns (Bt_{nr})

Aerial photo interpretation

Wooded bogs with forested permafrost bog and internal lawns are characterized by a heterogeneous surface that is dominated by wooded bog with a ground cover of *Sphagnum fuscum* and lichens, interspersed with densely forested bog having a scant ground cover dominated by feather mosses. Areas of densely forested bog are elevated above the surrounding wooded bog by > 40 cm, representing areas of relict permafrost and often are found in radiating patterns emanating from the bog crest. These

areas have been termed frost mounds (Beilman et al. 2001). Associated with areas of dense black spruce crown closure are open, wet, internal lawns dominated by *Sphagnum* and *Carex* containing dead trees. Internal lawns are generally 40 - 60 cm lower than the surrounding wooded, nonpermafrost bog and are irregular in shape. These internal lawns differ from those previously mentioned due to the presence of standing dead trees as well as their smaller maximum elevational differences to the surrounding bog.

Stratigraphic analyses of bogs with internal lawns from Alberta reveal an uppermost layer of about 30-50 cm of wet, oligotrophic species of *Sphagnum*, underlain by a thin layer of sedges followed by a layer dominated by *Polytrichum strictum* or *Pleurozium schreberi*, and abundant wood and/or black spruce needles. Beneath this last layer is a thick layer of a variety of more decomposed macrofossils, all indicating a habitat of dry wooded bog suggesting that substantial change occurred from a relatively dry, wooded bog habitat to a wet open lawn without transitional phases. Such changes are consistent with thermal subsidence of permafrost peatlands and the distribution of landforms comprising this wetland form (Vitt et al. 1994).

Wooded bogs with forested permafrost bog and internal lawns are recognized on aerial photos as medium toned wetlands without evidence of surface water movement. These bogs generally occur as islands or peninsulas within large, complex peatlands and have smooth, rounded margins. A “blotchy” pattern of distinctly darker and “fuzzy” lighter tones is present (Figure 11), representing permafrost bog and internal lawns respectively. Internal lawns are located within a nonpermafrost bog matrix, whereas collapse scars are surrounded by a matrix of peat plateau.

Vegetation

Wooded nonpermafrost bogs with forested permafrost bog and internal lawns represent a wetland type with a complex architecture of microhabitats. The nonpermafrost bog component is identical in its wetland architecture to wooded nonpermafrost bogs without internal lawns, while the forested permafrost bog component have a similar architecture to wooded permafrost bogs. In addition, the presence of internal lawns is reflected in the occurrence of lawn and carpet microhabitats that are typically absent in wooded nonpermafrost bogs without internal lawns.

As with layers and microhabitat covers, vegetation present within wooded nonpermafrost bogs with forested permafrost bog and internal lawns is complex. Vegetation of the nonpermafrost bog component is identical to that present in nonpermafrost bogs without internal lawns. Tree cover is almost exclusively restricted to *Picea mariana*, and vascular plant species are also similar to other bogs types. The shrub layer is dominated by *Ledum groenlandicum*, with *Chamaedaphne calyculata*, *Kalmia polifolia*, and *Rubus chamaemorus* present at lower cover values. Unlike permafrost bogs, sedges and shrubs of *Alnus rugosa* and *Salix* spp. are virtually absent. Herbs commonly include *Drosera* spp., *Eriophorum* spp., *Smilacina trifolia*, as well as *Vaccinium oxycoccus* and *Vaccinium vitis-idaea*. Ground cover in nonpermafrost bogs is dominated by *Sphagnum*: *S. fuscum*, *S. magellanicum*, and *S. angustifolium* in addition to brown mosses (*Aulacomnium palustre*, *Dicranum* spp. and *Mylia anomala*) and feather mosses (*Hylocomium splendens*, *Pleurozium schreberi*, and *Ptilium crista-castrensis*) as well as lichens (mostly species of *Cladina*, *Cetraria* and *Cladonia*), within a hummock and hollow architecture. In addition to these species, local areas of permafrost bog typified by tall, dense trees and a high percentage of bare peat/lichen and feathermoss communities are present as are local areas of internal lawn with carpets and lawns of *Carex* spp. and *Sphagnum*, typically *S. angustifolium*, *S. riparium*, and *S. russowii* with abundant snags (Beilman 2001). Forested permafrost bog and internal lawn areas are typically found adjacent to each other within the larger matrix of nonpermafrost bog. Pool microhabitat areas, representing wet areas where permafrost is actively melting are present at their interface with the nonpermafrost matrix. A typical wooded nonpermafrost bog with forested permafrost bog and internal lawns is shown in Figure 12.

Wooded bogs with internal lawns (Bt_{ni})

Aerial photo interpretation

This bog type is characterized by the presence of open, wet *Sphagnum-Carex*-dominated internal lawns, often containing partially buried stands of dead trees within a uniformly wooded bog island or peninsula. Internal lawns are 40 - 60 cm lower than the surrounding wooded bog surface and may occur in extensive, irregular patterns radiating from the bog island center, or in indistinct, nonradiating patterns. Although permafrost is absent, thin, seasonal frost layers can last well into late summer. Internal lawns

represent previous areas of permafrost that have historically degraded (Vitt et al. 1994, Halsey et al. 1995). Unlike wooded bogs with forested permafrost bogs and internal lawns, no areas of forested permafrost bog are present in this wetland type.

Wooded bogs with internal lawns are recognized on aerial photos as medium toned wetlands without any evidence of surface water movement (Figure 13). These bogs generally occur as islands or peninsulas within large, complex peatlands and have smooth, rounded margins. A "blotchy" pattern of "fuzzy" lighter tones is present within this wetland form representing islands of internal lawns.

Vegetation

Microhabitats and vegetation structure represent a transition between nonpermafrost bogs with forested permafrost bog (Bt_{ni}) and internal lawns and nonpermafrost bogs without internal lawns (Bt_{nn}). The typical nonpermafrost bog hummock-hollow microhabitats are present, however unlike the Bt_{nr} wetland class there are no areas of permafrost bog, hence the taller trees and associated areas of bare peat and high lichen/feather moss cover are absent. Internal lawns with carpets and small lawns are present with vegetation typical of other internal lawns with *Carex* spp. and *Sphagnum* spp. dominate. In contrast to the Bt_{nr} wetland class, pools are generally absent as a permafrost component is not present as a meltwater source.

Fens

Vegetative patterns that result from the presence of surface water flow allow for the distinction of fens from bogs. Fens have been subdivided on the basis of: 1) presence of landforms (strings and flarks) oriented perpendicular to surface water flow direction(s) in a parallel or reticulate pattern; 2) forest cover with open fens having $\leq 6\%$ cover, and wooded fens having $> 6\%$ cover of *Picea mariana* and/or *Larix laricina*; 3) presence of peat plateaus and internal lawns in wooded fens. Fen vegetation type can be subdivided into *Sphagnum*- and brown moss-dominated systems, each with distinctive vegetation communities that are partitioned in different spatial configurations across different wetland types.

Patterned fens (**Fopn** and **Ftpn**)

Aerial photo interpretation

Ribbed or patterned/string fens are a patterned form of geogenous peatland that are found in circumboreal and subarctic regions of the northern hemisphere (Troll 1944, Sjörs 1950; 1959; 1961, Ruuhijärvi 1960, Allington 1961, Heinselman 1963, Botch and Masing 1983, Zoltai et al. 1988, Vitt et al. 1996, Halsey et al. 1997). In addition, they have been reported in the arctic (Henoch 1960). Patterning is characterized by a string and flark (ridge and pool) pattern that runs parallel to surface elevation contours and perpendicular to the direction of water movement. Strings may span the entire fen in smooth or sinuous arcs that can subdivide and rejoin (Figures 11, 13, and 14). Pools, termed flarks by Andersson and Hesselman (1907) are found inbetween strings.

Unlike nonpatterned fens that are essentially level, ribbed fens have a slightly sloping surface of 0.1 to 1.0% (Zoltai et al. 1988). Detailed site studies in western Canada (Vitt et al. 1975, Zoltai et al. 1988) and elsewhere (Foster and King 1984, Seppälä and Koutaniemi 1985, Foster et al. 1988, Quinton and Roulet 1998, Charmann 1995), have shown that there is an elevational drop from flark to flark downslope. Strings tend to be closer together on steeper gradients and farther apart on shallower gradients. In addition, string orientation tends to become more sinuous and branching on lower slopes, with polygonal flark morphology—reticulate fens, typical of patterned fens with very low gradients (Zoltai et al. 1988).

Wetland inventories and methodologies conducted in Alberta (Zoltai et al. 1988, Vitt et al. 1996), recognize two basic types of patterned fens: wet patterned fens that have $\leq 6\%$ tree cover on strings (**Fopn**); and dry patterned fens that do have $> 6\%$ tree cover on strings (**Ftpn**). As with other fen types in Alberta, patterned fens have a wide range of chemical properties with pH from about 4.2 to >7.0 as well as an associated wide-ranging vegetation (Vitt et al. 1975, Slack et al. 1980, Zoltai et al. 1988). While the majority of patterned fens in the province are rich (Vitt et al. 1996); poor, patterned fens are known to occur and are associated with acidic substrates (Vitt et al. 1975), as well as along drainage divides. Hence, there are potentially four types of patterned fens in Alberta: wet and poor; wet and rich; dry and poor; and dry and rich.

Vegetation

Patterned fen microhabitats are typified by alternating areas of strings and flarks (Figure 15). While overall vegetation communities can be similar to wooded and open fens, it is the architecture, i.e. spatial pattern of these microhabitats that are the distinguishing feature of this wetland class. Vegetation on flarks is different than that found on strings due to the position of the water table (Vitt et al. 1975, Slack et al. 1980, Glaser 1983, Foster and King 1984, Charmann 1993). In rich fens (pH >5.5) (Slack et al. 1980, Zoltai et al. 1988), flark vegetation is typically dominated by *Carex chordorrhiza*, *C. lasiocarpa*, *C. limosa*, with *Menyanthes trifoliata*, *Utricularia intermedia*, and *U. minor* also present. Mosses are typically *Campylium* spp. and *Scorpidium scorpioides*, as well as species of *Meesia triquetra* and *Drepanocladus* spp. String vegetation is comprised of the shrubs *Andromeda polifolia*, *Betula glandulosa*, *Ledum groenlandicum*, *Salix candida*, and *S. pedicellaris* with trees of *Larix laricina* and *Picea mariana* present on drier ridges. Mosses are typically dominated by *Aulacomnium palustre*, *Tomenthypnum nitens*, *Sphagnum angustifolium* and *Sphagnum warnstorffii*, with *Dicranum undulatum*, *S. fuscum*, and *Pleurozium schreberi* commonly found on drier strings. Vegetation in poor, patterned fens (pH 4.2 – 5.5) (Vitt et al. 1975, Zoltai et al. 1988) is dominated by *Carex limosa* and *Menyanthes trifoliata* as well as species of *Drepanocladus* and *Sphagnum* in flarks. String vegetation is similar to that of bogs (Vitt et al. 1975, Zoltai et al. 1988, Belland and Vitt 1995) and is typified by *Picea mariana*, *Ledum groenlandicum*, *Sphagnum fuscum*, and *S. magellanicum*.

While vegetation communities between these four patterned fen types differ, they are each not unique when compared to other open fen types on the basis of layer (Figure 2) and microhabitat (Figure 3) covers. For example a rich, nonpatterned treed fen can have similar species to a rich patterned fen with trees present on strings, however the architecture of the vegetation and microhabitats will be partitioned differently in space. Rich nonpatterned fens will contain hummocks and hollows that are distributed in an apparently random pattern over the fen surface. In contract, rich patterned fens with trees on the strings will have an ordered pattern of alternating flarks (with hollow vegetation) and strings (with hummock vegetation).

Nonpatterned, open, shrub-dominated fens (**Fons**)

Aerial photo interpretation

Nonpatterned, open, shrub-dominated fens can be recognized on aerial photographs by the presence of surface water movement and a lack of patterning (Figure 16). This fen type can be distinguished from other nonpatterned fen types by its medium gray tone that has a tendency to be "blotchy", reflecting the variation in shrub canopy closure, and on small-scale photos by the crenulate nature of the shrub cover. Nonpatterned, open, shrub-dominated fens can be poor or rich (Vitt and Chee 1990, Beckingham and Archibald 1996).

Vegetation

Nonpatterned, open, shrubby fens are lacking taller canopy layers, though they support shrubs of *Betula pumila*, and *Salix pedicellaris* as well as numerous other willow species (i.e. *S. candida*, *S. discolor*, *S. maccalliana*, *S. myrtillifolia*, *S. planifolia*, and *S. serissima*). Common graminoids, *Carex*, and herbs include *Calamagrostis canadensis*, *Carex aquatilis*, *Carex pauciflora*, *Calla palustris*, *Galium trifidum*, *Potentilla palustris*, *Smilacina trifolia*, and *Stellaria longifolia*. Bryophytes are dominated by *Sphagnum angustifolium* and *Tomenthypnum nitens*, with other *Sphagnum* spp. common in poor shrubby fens. In addition, *Aulacomnium palustre*, *Brachythecium* spp., and *Helodium blandowii* are common, although cover values are generally low.

Nonpatterned, open, shrubby fens are separated from wooded wetlands in the layer ordination (Figure 2) reflecting their dominance by low shrubs (< 2 m) and high graminoid covers. Wet microhabitats (lawns and carpets) are associated with Fons more than wooded wetlands and hence nonpatterned, open, shrubby fens are isolated from wooded wetlands on the microhabitat ordination (Figure 3). This wetland type is however not readily distinguishable on the basis of layer and/or microhabitat from nonpatterned, open graminoid-dominated and patterned fens as sites of these wetland types overlap (Figure 2 and 3).

Nonpatterned, open, graminoid-dominated fens (Fong)

Aerial photo interpretation

Nonpatterned, open, graminoid-dominated fens are characterized by the presence of a continuous *Carex* cover with $\leq 6\%$ tree cover and $< 25\%$ shrub cover. Open, graminoid dominated fens can be distinguished from other nonpatterned fen types on airphotos by a light to very light gray tone with a smooth texture (Figures 16 and 17). This peatland type can grade into wet meadows associated with uplands and non-peat forming wetlands associated with aquatic ecosystems (marshes and shallow open waters). Non-peat forming wetlands are found in areas of fluctuating water level such as along the margins of lakes and streams, and generally lack a bryophyte layer and associated peat accumulation.

Vegetation

Open, graminoid-dominated poor fens occupy many places on the landscape. They can occur as collapse scars in association with peat plateaus and as laggs associated with bog islands. In addition they can occur in small isolated basins; and as flat, featureless fens that slope gently in the direction of drainage (Figure 18) and may be poor, moderate-rich, or extreme-rich (Vitt and Chee 1990, Nicholson and Gignac 1995). Occasional low shrub ($< 25\%$ cover can be found) and can include *Betula pumila*, *Chamaedaphne calyculata*, *Rubus acaulis*, *Salix myrtillofolia* and *Salix pedicellaris*. Sedges such as *Carex aquatilis*, *C. diandra*, and *C. limosa* in addition to the almost ubiquitous herb *Potentilla palustris* dominate the understory. Rich, open graminoid-dominated fens are dominated by a ground cover of *Aulacomnium palustre*, *Calliergon giganteum*, *Drepanocladus exannulatus*, and *Drepanocladus vernicosus*, while poor, open graminoid-dominated fens support a ground cover of *Sphagnum* that can include species: *S. angustifolium*, *S. centrale*, *S. fallax*, *S. jenseii*, *S. riparium*, *S. russowii*, *S. squarrosum*, *S. subsecundum*, and *S. teres*.

As with nonpatterned, open shrubby fens, open graminoid-dominated fens have a restricted number of vegetation layers, with graminoid and aquatic layers dominating (Figure 2). Microhabitats are also restricted as those associated with tree cover and tree derived substrates are generally absent. Lawns represent the largest microhabitat cover for nonpatterned, open graminoid-dominated fens, with grass tussocks and root mounds also being important (Figure 3). Nonpatterned, open graminoid fens are

however, not well distinguished from other open fen types (Fons and Fopn) as indicated by their overlap with sites of these wetland types on both the layer and microhabitat ordination diagrams (Figures 2 and 3).

Nonpatterned, wooded fens with no internal lawns (Ftnn)

Aerial photo interpretation

Nonpatterned, wooded fens with no internal lawns have >6% tree cover of some combination of *Picea mariana* and/or *Larix laricina*. An understory of shrubs of *Betula* and *Salix* is not uncommon. The ground cover of wooded fens can be *Sphagnum*- or brown moss- dominated. Wooded fens with no internal lawns have a smooth, homogenous surface that is medium gray in tone and has a "velvety" texture on aerial photos (Figure 17). The boundary between wooded fen and mineral upland can be difficult to distinguish and is determined on the basis of slope with wooded fens being found only on level surfaces. Tree density and height are also important factors in fen identification, and are a function of climatic and substrate conditions, hence should be locally derived.

Vegetation

Nonpatterned, wooded fens with no internal lawns occupy similar places on the landscape as open fens, and are often found in small isolated basins; and as flat, featureless fens that slope gently in the direction of drainage. They may be poor, moderate-rich, or extreme-rich (Vitt and Chee 1990, Nicholson and Gignac 1995), with each fen type having a distinctive vegetation community and associated water chemistry. Poor fens generally have a pH of <5.5, moderate-rich fens range between 5.5-7.0, while extreme-rich fens are generally > 7.0 (Vitt 1994). Vegetatively they fall between wooded bogs and open graminoid and shrubby fens (Figure 2), as they contain species common to both. Drier vegetation, common to bogs is represented by hummock species, while vegetation common to open fens occurs in wet hollows, carpets, lawns, and pools. As with vegetation, micro-habitats present in nonpatterned, wooded fens also fall between wooded bogs and open graminoid and shrubby fens (Figure 3), as aspects of both these wetland types occur in nonpatterned wooded fens.

The forest canopy in nonpatterned, wooded fen with no internal lawns consists of varying amounts of *Picea mariana* and/or *Larix laricina* along the poor to moderate-rich to extreme-rich gradient. In general, poor, wooded fens have a significant component of *Picea mariana*, generally $\geq 20\%$, with *Larix laricina* ubiquitously present, though in relatively low amounts ($<20\%$) (Beckingham and Archibald 1996). In contrast, rich fens have a significant amount of *Larix laricina* ($\geq 20\%$) and lower amounts of *Picea mariana* (Beckingham and Archibald 1996). Abboud et al. (2002) distinguished between moderate-rich and extreme-rich fens on the basis of tree cover. Extreme-rich fens are dominated by *Larix laricina*, while moderate-rich fens represented a mix of both species.

Occasional low shrub ($< 25\%$ cover can be found) and can include *Betula pumila*, *Rubus acaulis*, *Rubus chamaemorus*, *Ledum groenlandicum*, *Salix myrtilifolia* and *Salix pedicellaris*. Herbs and low shrubs commonly include *Caltha palustris*, *Galium trifidum*, *Menyanthes trifoliata*, *Potentilla palustris*, *Smilicina trifolia*, *Calamagrostis canadensis*, *Vaccinium oxycoccus*, and *V. vitis-idea*. In addition, sedges that include *Carex aquatilis*, *C. canescens*, *C. chordorrhiza*, *C. diandra*, *C. disperma*, *C. gynocrates*, *C. interior*, *C. lasiocarpa*, *C. leptalea*, *C. limosa*, *C. rostrata*, *C. tenuiflora*, and *C. trisperma* are common.

Brown mosses in rich fens, and *Sphagnum* in poor fens dominate the ground cover of nonpatterned, wooded fens without internal lawns. As in other peatland types, species presence is a function of the position relative to the water table as well as surface water chemistry (Gignac et al. 1991). Table 2 outlines common species found in each wooded fen type along the hummock-hollow-pool microhabitat gradient. While some species are found in more than one fen type, the common bryophytes found in each microhabitat within a fen type are unique.

TABLE 2: Common bryophyte species found in nonpatterned wooded fens along a moisture gradient (modified from Vitt 1994).

	POOR FEN	MODERATE-RICH FEN	EXTREME-RICH FEN

Nonpatterned, wooded fens with islands of forested peat plateau and internal lawns (Ftnr)

Aerial photo interpretation

In some wooded fens, small islands of permafrost can be found that are forested exclusively with *Picea mariana* (frost mounds). These forested islands are surrounded and associated with wetter and lower areas than the surrounding wooded fen representing internal lawns. These lawns contain standing, dead trees and are dominated by graminoid species and wetter species of *Sphagnum* or brown moss than the surrounding wooded fen. A woody debris layer is present stratigraphically within internal lawns at a depth of 20-40 cm. Plants, usually growing under drier conditions, such as *Pleurozium schreberi* or *Tomenthypnum nitens*, have been found in this woody debris layer. Remnants of these forested "islands" are still present around the lawns and are recognized by a narrow zone of denser tree cover dominated by *Picea mariana*. This results in a "ghost" image of the former extent of the peat plateau that has degraded (Vitt et al. 1994).

A heterogeneous tone characterizes aerial photos of this wetland form; with a medium toned matrix interspersed with distinct, darker toned peat plateaus and "fuzzy", lighter toned internal lawns (Figure 19). Internal lawns can be ringed with a slightly darker toned border (Figures 19 and 20). Islands of peat plateaus and associated internal lawns in wooded fen are generally located along the margins of mineral uplands or large bogs.

Vegetation

Nonpatterned, wooded fens with islands of forested peat plateau and internal lawns represent a wetland type with a complex architecture of microhabitats (Figure 21). The nonpatterned wooded fen component

is identical in its microhabitat architecture to nonpatterned wooded fens without internal lawns, while the forested permafrost bog component has similar microhabitat architecture to wooded permafrost bogs. In addition, the presence of internal lawns is reflected in the occurrence of typically small lawn and carpet microhabitats that are typically restricted in area (small) in wooded nonpermafrost fens without internal lawns. As a result of this complex microhabitat architecture, canonical correspondence analyses of nonpatterned, wooded fens with islands of forested peat plateau and internal lawns sites fall between wooded bogs and nonpatterned, wooded fens without internal lawn sites (Figure 2).

As with layers and microhabitat covers, vegetation present within nonpatterned wooded fens with forested permafrost bog and internal lawns is complex. Vegetation of the nonpatterned wooded fen component is identical to that present in nonpatterned wooded fens. Tree cover is composed of varying combinations of *Larix laricina* and *Picea mariana*, with differences in dominance a function of fen type. In addition, local areas of permafrost bog typified by tall, dense trees and a high percentage of bare peat/lichen and feathermoss communities are present as are local areas of internal lawn with carpets and lawns of *Carex* spp. with brown moss dominant in rich fens and *Sphagnum* species dominate in poor fens. As with their bog counter-parts internal lawns in fens typically contain abundant snags from the former permafrost bog (Figure 21). Forested permafrost bog and internal lawn areas are typically found adjacent to each other within the larger matrix of nonpatterned wooded fen, with pool microhabitat areas present at the interface, representing wet areas where permafrost is actively melting. Canonical correspondence analyses of vegetation from stands within nonpatterned, wooded fens with islands of forested peat plateau and internal lawns fall between wooded bogs and nonpatterned, wooded fens without internal lawns as would be expected (Figure 3). A typical nonpatterned wooded fen with forested permafrost bog and internal lawns is shown in Figure 21.

Nonpatterned, wooded fens with islands of internal lawns (Ftni)

Aerial photo interpretation

As with the previous wetland form, islands of internal lawns occur as wetter depressions in the surrounding wooded fen; however, unlike the previous wetland form, no small islands forested exclusively

with *Picea mariana* are present. Aerial over flights reveal the presence of dead trees tilted in random directions on the fen lawns, indicating the former existence of densely wooded, small permafrost bodies. Internal lawns are ringed by a narrow zone of denser tree cover dominated by *Picea mariana* marking the former extent of peat plateau. Internal lawns have a ground cover containing wetter species of *Sphagnum* or brown moss than the surrounding wooded fen that may be poor, moderate-rich, or extreme-rich.

As with the previous wetland form a heterogeneous tone characterizes aerial photos of wooded fens with islands of internal lawns. A medium toned matrix is interspersed with “fuzzy”; lighter toned internal lawns that can be ringed with a slightly darker toned border (Figure 22). Islands of internal lawns in wooded fen are generally located along the margins of mineral uplands or large bogs.

Vegetation

Microhabitats and vegetation within this wetland type represents a transition between nonpatterned, wooded fen with forested permafrost bog and internal lawns and nonpatterned, wooded fen without internal lawns. Species presence is largely determined by fen type, however unlike the Ftnr wetland class there are no areas of permafrost bog, hence the taller trees and associated areas of bare peat and high lichen/feather moss cover are absent. Internal lawns with carpets and lawns are present with vegetation typical of other internal lawns with vegetation dominated by *Carex* spp. and *Sphagnum* in poor fens, while brown mosses dominate in rich fens. In contrast to the Ftnr wetland class, large pools are generally absent as an actively melting permafrost component is not present (Figure 23). As a result of this complex vegetation architecture nonpatterned, wooded fens with internal lawns are not distinguishable on the layer (Figure 2) or microhabitat (Figure 3) ordination. However, the spatial partitioning of these layers and microhabitats into separate components of the wetland type reflects its distinctness (Figures 2 and 3).

Marshes (Mong)

Aerial photo interpretation

Marshes are distinguished from other wetland forms by lack of tree or shrub cover resulting in a light tone on aerial photographs. Unlike open, graminoid-dominated fens, marshes require frequent flooding and are associated with fluctuating water levels. In Alberta, marshes may be saline (Na) or calcareous (Ca) and can be distinguished from open, graminoid-dominated fens by their association with the margins of streams and lakes. Marshes are also distinguished on aerial photos by their association with shallow open water (Figure 24).

Vegetation

Marshes are open systems that do not support a tree or shrub layer. The vegetation is dominated by forbs and graminoids. Common forbs include *Epilobium ciliatum*, *Mentha arvensis*, *Polygonum amphibium*, *Potentilla palustris*, and *Typha latifolia* (Figure 25). Typical graminoids include species of *Carex*, *Juncus*, *Phragmites*, and *Scirpus*, in addition to *Calamagrostis canadensis* and *Eleocharis palustris*. Bryophytes, common in open fens, are generally absent or have very low cover values of brown mosses.

Swamps

Swamps are recognized by their location in the landscape next to water bodies that flood frequently or are associated with fluctuating water levels such as is found along peatland margins. Unlike marshes, which do not support a shrub or tree cover due to seasonally wet or regional climatic conditions, swamps are wooded or shrub covered.

Coniferous swamps (Sfnn and Stnn)

Aerial photo interpretation

Coniferous swamps are forested and have a dense tree cover that is dominated by some combination of *Picea mariana* and *Larix laricina*. They occur in Alberta in association with floodplains and streams and along the margins of some peatland complexes (Figure 26). In addition, they are often located on broad plains in association with groundwater discharge either from springs or seeps. Coniferous swamps are

recognized from aerial photographs by their position in the landscape, level topography, nonuniform tree height, and dense forest cover (Figure 27). Tree height is greater in swamps than in fens as organic accumulation is < 40 cm. Correct classification of forested *Picea mariana* swamps is difficult as canopy characteristics bear strong resemblance to upland, non-wetland *P. mariana* stands. Landscape position is often key to recognition of coniferous swamps, and fieldwork is required.

Vegetation

Coniferous swamps have a diverse assemblage of species that may be present. As this wetland type often represents a forested transition between upland and aquatic or peatland communities, species occurrences are often a function of adjacency and/or the history of paludification at a site. The tree layer is generally dominated by some combination of *Picea mariana* and *Larix laricina*. Minor species may include but are not restricted to *Abies balsamea*, *Betula papyrifera*, *Picea glauca*, *Pinus banksiana*, *Pinus contorta*, *Populus balsamifera*, and *Populus tremuloides*. Shrubs are ubiquitous and are represented by *Alnus crispa*, *A. tenuifolia*, *Cornus canadensis*, *Cornus stolonifera*, *Ledum groenlandicum*, *Linnaea borealis*, *Rosa acicularis*, *Rubus idaeus*, *Viburnum edule*, and *Vaccinium myrtilloides*, as well as species of *Ribes* and *Salix* that are generally > 2m in height. The herb layer is commonly composed of species that may include *Aralia nudicaulis*, *Calamagrostis canadensis*, *Lycopodium annotinum*, *Mertensia paniculata*, *Mitella nuda*, *Petasites palmatus*, *Rubus pubescens*, and *Vicia americana*, as well as species of *Carex* and *Equisetum*. Bryophytes are dominated by *Climacium dendroides*, *Hylocomium splendens*, *Ptilium crista-castrensis*, and *Pleurozium schreberi* in drier microhabitats and species of *Brachythecium* in wetter microhabitats.

Deciduous swamps (Sons)

Aerial photo interpretation

Deciduous swamps lack a tree cover and have >25% shrub cover, dominated by species of *Salix* that generally grow above 2 m. Bryophytes are uncommon due to fluctuating water tables. Deciduous swamps occur along floodplains and stream terraces, and along peatland margins. On aerial photographs deciduous swamps are recognized by their position in the landscape, a medium to dark tone, and by a "blotchy" texture that reflects the variation in shrub canopy closure. On small scale aerial

photographs shrub vegetation has a crenulate pattern that is easily distinguished (Figure 28). Deciduous swamps are differentiated from open, shrub-dominated fens by shrub size and landscape position.

Vegetation

The shrub layer of deciduous swamps is commonly composed of species of *Salix* (Figure 29), as well as *Alnus tenuifolia* and *Betula glandulosa*. Herbaceous vegetation is dominated by *Carex* spp. and can include such species as *Calamagrostis canadensis*, *Caltha palustris*, *Galium trifidum*, *Heracleum lanatum*, *Potentilla palustris* and *Typha latifolia*.

Shallow Open Waters (Wonn)

Aerial photo interpretation

This wetland class is distinguished by its association with other wetland forms, particularly marshes in the south and thermokarst basins in the north associated with peat plateaus. On aerial photographs shallow open waters are recognized as small pools of water with smooth, to irregular margins that may be distinct or gradational (Figure 26). Mottling on the water surface is not uncommon and is caused by the presence of emergent vegetation. Water bodies with scalloped margins are often found within peatlands. These water bodies are generally not considered to be shallow open waters as they are greater than 2 m in depth and function as aquatic systems.

Vegetation

Shallow open water wetlands represent a transition between terrestrial and truly aquatic ecosystems with both emergent and submergent species present. They are characterized by species common to both terrestrial and aquatic systems, with species of *Potamogeton*, *Ranunculus*, and *Scirpus* commonly found in addition to *Callitriche verna*, *Ceratophyllum demersum*, *Hippuris vulgaris*, *Lemna minor*, *Myriophyllum spicatum*, *Nuphar variegatum*, *Polygonum amphibium*, and *Typha latifolia*.

FIGURE 4: Aerial photograph of veneer bogs (Boxc/n) from the Caribou Mountains, Alberta (59° 25'N and 115° 38'W). The veneer bogs are characterized by their low angle of slope and by the presence of runnels that contain denser, taller trees and mimic drainage patterns. On flat terrain these veneer bogs grade into wooded, permafrost dominated bogs (Btxc/n).

FIGURE 5: Ground view of a veneer bog. Densely treed areas represent runnels, while open shrubby areas are the inter-runnels. Permafrost is present throughout this wetland landform.

FIGURE 6: Aerial photograph of an extensive wooded permafrost bog with collapse scars from the Birch Mountains of Alberta (57° 47'N and 112° 31'W). The development of collapse scars represented by the light, bright tones on the photo have been, in some cases, linked to fire (Zoltai 1993). Burned areas (darker tone) have larger collapse scars that have integrated with drainage resulting from temporary degradation of permafrost. As vegetation is reestablished, permafrost will expand and the collapse scars will decrease in size and surface drainage will become less ordered.

FIGURE 7: Wooded permafrost bog forested exclusively with *Picea mariana* from the Birch Mountains in northern Alberta. Collapse scars represent the light grey tone on the photo and are areas that do not contain permafrost.

FIGURE 8: Collapse scar from the Caribou Mountains, Alberta. The collapse scar is dominated by species of *Carex* and wet loving *Sphagnum*.

FIGURE 9: Bog islands with no internal lawns in the area of Grande Prairie, Alberta (54° 02' N and 118° 42'W). These bog islands (b) have developed as peninsulas in areas of water stagnation, within a larger fen (f). Arrows point to wetter, open areas of the fen surrounding the bog margin termed water tracks.

FIGURE 10: Typical ground view of a wooded bog from northern Alberta. The tree layer is exclusively forested with *Picea mariana*, with *Sphagnum* spp. dominating the ground cover.

FIGURE 11: These wooded bogs with areas of forested, permafrost bog and internal lawns (Btnr) are located near McClelland Lake, Alberta on the edge of a large, patterned fen (Fopn) (56° 25'N and 111° 15'W). The slightly elevated bogs lack surface water movement in contrast to the surrounding fen. Darker toned areas within the bog islands represent areas of forested, permafrost bog, while lighter toned areas within the bog islands represent islands of internal lawns.

FIGURE 12: Typical view from an internal lawn looking into a relict permafrost body forested exclusively with *Picea mariana*. Unlike collapse scars, internal lawns have dead snags present.

FIGURE 13: Aerial photograph of wooded bogs with internal lawns (Bt_{ni}) from eastern Alberta (55° 28' N and 111° 48' W). These bogs are occurring as islands within a larger patterned fen (Fop_n/Ftp_n). Arrows pointing to the irregularly shaped lighter toned areas are the internal lawns within the bog islands. The most westerly bog island (Bt_{xc/n}) still contains a substantial amount of permafrost even at this southerly latitude.

FIGURE 14: Patterned fen from northwestern Alberta (59° 01' N and 118° 23' W). The patterned fen has a reticulate pattern of dry strings (s) and wet flarks (f). In some cases permafrost has developed in the strings resulting in the formation of small, linear wooded permafrost bogs.

FIGURE 15: Helicopter view of a patterned fen near Audet Lake, Alberta (57° 36'N and 110° 51'W).

FIGURE 16: Open, shrub-dominated (Fons) and graminoid-dominated (Fong) fens, and a tree-dominated (Ftnn) fen from central Alberta (54° 37' N and 113° 48' W).

FIGURE 17: Fens within a dune complex located along the Athabasca River (54° 23' N and 115° 27' W). Light toned peatland areas consist of open, graminoid-dominated fens (o), while darker peatland areas are wooded fens with no internal lawns (t).

FIGURE 18: Nonpatterned, open graminoid-dominated fen from east central Alberta dominated by *Carex*, *Equisetum*, *Eriophorum*, and *Triglochin*.

FIGURE 19: Aerial photograph of a peatland complex from central Alberta 56° 33' N and 112° 32' W. This peatland is composed of a wooded fen with areas of internal lawns (Ftnr), and areas of wooded fen with internal lawns (Ftni). Wooded bogs with forested peat plateau and internal lawns (Btnr) are also present throughout.

FIGURE 20: Aerial photograph of a nonpatterned wooded fen with forested permafrost bog and internal lawns.

FIGURE 21: Nonpatterned wooded fen in foreground with internal lawn and wooded permafrost bog in background. Site is from northeastern Alberta near 56° 30' N and 112° 30' W.

FIGURE 22: Nonpatterned wooded fen with internal lawns from air. Arrows point to internal lawns.

FIGURE 23: Helicopter view of nonpatterned wooded fen with internal lawns. Taller rings of trees represent the margin of internal lawns.

FIGURE 24: Aerial photo of marsh surrounding pond of shallow open water south of Red Earth Creek, Alberta 56° 13'N and 115° 45'W.

FIGURE 25: Marsh/shallow open water transition from north of Devon, Alberta.

FIGURE 26: Aerial photo of a wooded swamp located along the northwest shore of Otasan Lake, Alberta.

FIGURE 27: Wooded swamp in central background of photo with wooded nonpatterned fens flanking either side.

FIGURE 28: Aerial photo of a shrubby *Salix* spp. swamp from central Alberta. Shrubby swamp runs from south to north through center of photo.

FIGURE 29: *Salix* swamp along stream channel from Elk Island National Park, Alberta.

6.0 ALIGNMENT OF ALBERTA WETLAND INVENTORY WITH ECOSITE PHASE CLASSIFICATION

The ecosite classification system developed by Beckingham and Archibald (1996) is often used in conjunction with the Alberta Wetland Inventory Standards. Use of similar terminology for some ecosites and ecosite phases as Wetland Inventory Standards, and lack of some terminology in the ecosite and ecosite phase classification system has lead to some confusion among users. Here we present a concordance table that is focused on addressing the similarities and dissimilarities between the two classification systems.

The Alberta Wetland Inventory Standards recognizes the presence of permafrost in Alberta. Permafrost is generally found in bogs as larger peat plateaus (BTXN and BTXC) as well as veneer bogs (BOXN and BOXC), or as small frost mounds (*sensu stricto* Beilman et al. 2001) present in both bogs (BTNR) and fens (FTNR). The ecosite and ecosite phase classification of Beckingham and Archibald (1996) does not recognize permafrost in Alberta, and the Cryosolic Soil Order is not included in the field guide, though some plots particularly in the Subarctic Subregion may have contained permafrost (ecosite phases e1 and f1).

Bogs are recognized as a separate ecosite for all four subregions in Beckingham and Archibald (1996) and are represented by treed and shrubby ecosite phases: Boreal Mixedwood (BM): i1 and i2; Boreal Highlands (BH): h1 and h2; Subarctic (SB): f1 and f2; Canadian Shield (CS): f1 and f2. With the exception of the Shrubby Bog ecosite phase of the Canadian Shield Subregion (f2), all the bog ecosite phases appear to have concordance with the Alberta Wetland Inventory concept of bogs. The shrubby bog ecosite phase of the Canadian Shield did not have concordance with AWI defined bogs as organic thickness of all plots (n = 2) was less than 40 cm. In addition to the bog ecosites, additional ecosite phases in both the BM (g1 and h1), BH (i1), and SB (e1) subregions are dominated by black spruce and have ≥ 40 cm of organics. The organic thickness suggests that these ecosite phases are peatlands, with the lack of *Larix laricina* suggestive of bog vegetation, though some plots could also be representative of poor fens.

Wooded fens, both poor and rich, are recognized by Beckingham and Archibald (1996). In general ecosite phases identified as wooded poor and rich fens are in concordance with the Alberta Wetland Inventory Standards. The exceptions are the treed poor fen ecosite phase (i1) in the Boreal Highlands and Subarctic Subregions. Treed poor fens in the Boreal Highlands appear more similar to bogs as they do not support *Larix laricina* as a typical species in the tree layer (n = 1). Treed poor fens identified by Beckingham and Archibald (1996) in the Subarctic subregion are not in concordance with the Alberta Wetland Inventory Standards as over half of the plots have an organic thickness of <40 cm. These plots are more characteristic of coniferous swamps.

Shrubby fens are also recognized by Beckingham and Archibald (1996), though concordance with AWI is poor. Lack of concordance is generally a function of plots that have <40 cm of organics, and for this reason are more typical of deciduous swamps. In addition, the presence of *Picea glauca* in the shrubby rich fen community of the Boreal Highlands, and lack of bryophytes in the shrubby rich fen community of the Canadian Shield are also more typical of swamps than fens.

Graminoid-dominated open fens are found in all subregions and can be both poor and rich. While graminoid poor fens are not recognized in Beckingham and Archibald (1996) they are present within Alberta and commonly occur as lags associated with bog islands or in association with collapse scars in the Subarctic subregion. In addition they are often found in association with acidic bedrock and in topographic highs in the landscape (Vitt et al. 1975, Halsey et al. 1997). Graminoid rich fens are present as ecosite phases, and are recognized within all subregions. While 60% of the plots that were utilized to define this ecosite phase appear to be in concordance with AWI, 40% are not. Of the plots that do not appear to be in concordance, difference is a function of organic thickness. Graminoid-dominated plots with <40 cm organics appear more typical of marshes in AWI.

While wooded swamps are not implicitly recognized within the ecosite phase classification, several ecosite phases are dominated by some combination of *Picea mariana* and *Larix laricina* but have an organic thickness of <40 cm. These ecosite phases include BM: g1 and h1; BH: g1; SB: e1; and CS: d1. Though there is not perfect concordance as some plots have >40 cm of organics, these ecosite phases

can be typically viewed as wooded swamps. In addition, ecosite phases with communities containing species such as *Abies balsamea*, *Picea glauca*, and *Populus balsamifera* (BM: f1; BH: f1; SB: d1, d2, and d3; and CS: e1 and e2) are typically not considered swamps. However, when these species are found in association with a tree layer dominated by some combination of *Picea mariana* and *Larix laricina* these ecosite phases can be recognized as swamps.

Shrubby swamps and marshes are typically not recognized by the ecosite phase classification with the exception of marshes in the Boreal Mixedwood Subregion. However, organic depths of <40 cm for shrubby rich fens within the Boreal Mixedwood (k2 ecosite phase) and Subarctic (h2 ecosite phase) would likely represent shrubby swamps. Organic depths of <40 cm for graminoid fens within all subregions (BM: k2; BH: h2; SB: h2, and CS: h2) likely represent marshes.

TABLE 3: Concordance of Alberta Wetland Standards with Ecosite Phase Classification of Beckingham and Archibald (1996).

Peatlands

AWI	Boreal Mixedwood	Boreal Highlands	Subarctic	Canadian Shield
Bogs (B _ _ _) -permafrost or internal lawns may or may not be present -≥ 40 cm organics -forested exclusively with <i>Picea mariana</i>	Ecosite phase g1 (Labrador tea-subhygric Sb-Pj) -10% of plots have ≥80 cm organics -stands support an average of ≥10% <i>Pinus banksiana</i>	Ecosite phase h1 and h2 (Treed and shrubby bogs) -Concordance	Ecosite phase e1 (Labrador tea-hygric Sb-Pi) -50% of plots have ≥80 cm organics -stands support an average of ≥5% <i>Pinus contorta</i>	Ecosite phase f1 (Treed bog) -Concordance
	Ecosite phase h1 (Labrador tea/horsetail Sw-Sb) -20% of plots have ≥40 cm organics -Lack of <i>Larix laricina</i> within the recognized plant community is more suggestive of bog vegetation			
Wooded fens (FT _ _) -≥ 40 cm organics -forested with some combination of <i>Picea mariana</i> and <i>Larix laricina</i>	Ecosite phase i1 and i2 (Treed and shrubby bogs) -Concordance	Ecosite phase i1 (Treed poor fen) -Lack of <i>Larix laricina</i> within the recognized plant community is more suggestive of bog vegetation	Ecosite phase f1 and f2 (Treed and shrubby bog) -Concordance	Ecosite phase f2 (Shrubby bog) -100% of plots have < 40cm of organics
	Ecosite phase j1 (Treed poor fen) -Concordance	Ecosite phase i1 (Treed poor fen) -Lack of <i>Larix laricina</i> within the recognized plant community is more suggestive of bog vegetation	Ecosite phase i1 (Treed poor fen) -60% of plots have < 40 cm organics	Ecosite phase j1 (Treed poor fen) -Concordance
Shrubby fens (FONS) -≥ 40 cm organics -shrub layer generally ≤ 2m -bryophytes common in ground layer	Ecosite phase k1 (Treed rich fen) -Concordance	Ecosite phase j1 (Treed rich fen) -Concordance	Ecosite phase h1 (Treed rich fen) -Concordance	Ecosite phase k1 (Treed rich fen) -Concordance
	Ecosite phase j2 (Shrubby poor fen) -30% of plots have <40 cm organics Ecosite phase k2 (Shrubby rich fen) -50% of plots have <40 cm organics	Ecosite phase i2 (Shrubby poor fen) -Concordance Ecosite phase j2 (Shrubby rich fen) -Presence of <i>Picea glauca</i> tree layer not typical	Ecosite phase g2 (Shrubby poor fen) -Concordance Ecosite phase h2 (Shrubby rich fen) -100% of plots have <40 cm organics	Ecosite phase g2 (Shrubby poor fen) -100% of plots have <40 cm organics Ecosite phase h2 (Shrubby rich fen) -bryophytes not identified as part of plant community
Graminoid fens (FONG and FOPN) -≥ 40 cm organics -bryophytes common in ground layer	-Open poor fens are not recognized Ecosite phase k3 (Graminoid rich fen) -40% of plots have <40 cm organics	-Open poor fens are not recognized Ecosite phase h3 (Graminoid rich fen) -40% of plots have <40 cm organics	-Open poor fens are not recognized Ecosite phase h3 (Graminoid rich fen) -40% of plots have <40 cm organics	-Open poor fens are not recognized Ecosite phase h3 (Graminoid rich fen) -40% of plots have <40 cm organics

TABLE 3: continued.

Nonpeat-accumulating wetlands

AWI	Boreal Mixedwood	Boreal Highlands	Subarctic	Canadian Shield
Wooded swamps (STNN) -<40 cm of organics -dominated by some combination of <i>Picea mariana</i> and <i>Larix laricina</i>	Ecosite phase f1 (Horsetail Pb-Aw) -Defined vegetation community not in concordance, however dominance of some combination of <i>Picea mariana</i> and <i>Larix laricina</i> with <i>Picea glauca</i> and <i>Populus balsamifera</i> and other species is suggestive of this ecosite phase.	Ecosite phase f1 (Horsetail Sw) -Defined vegetation community not in concordance, however dominance of some combination of <i>Picea mariana</i> and <i>Larix laricina</i> with <i>Picea glauca</i> and <i>Abies balsamea</i> and other species is suggestive of this ecosite phase.	Ecosite phase d1, d2, and d3 (Horsetail Pb-Bw, Aw-Sw, and Sw) -Defined vegetation community not in concordance, however dominance of some combination of <i>Picea mariana</i> and <i>Larix laricina</i> with <i>Picea glauca</i> and <i>Populus balsamifera</i> and other species is suggestive of this ecosite phase.	Ecosite phase d1 -Concordance
	Ecosite phase g1 (Labrador tea-subhygric Sb-Pj) -10% of plots have ≥ 80 cm organics	Ecosite phase g1 (Labrador tea-hygric Sb-Pj) -Concordance	Ecosite phase e1 (Labrador tea-hygric Sb-Pl) -50% of plots have ≥ 80 cm organics	Ecosite phase e1 and e2 (Willow/horsetail Aw-Bw-Pb and Aw-Sw-Sb) -Defined vegetation community not in concordance, however dominance of some combination of <i>Picea mariana</i> and <i>Larix laricina</i> with <i>Picea glauca</i> and <i>Populus balsamifera</i> and other species is suggestive of this ecosite phase
	Ecosite phase h1 (Labrador tea/horsetail Sw-Sb) -20% of plots have ≥ 40 cm organics			
Shrubby swamps	Not recognized	Not recognized	Not recognized	Not recognized
Marsh -<40 cm organics -bryophytes not typically abundant	Ecosite phase l1 (Marsh) -Concordance	Not recognized	Not recognized	Not recognized
Shallow Open Water	Not recognized	Not recognized	Not recognized	Not recognized

APPENDIX 1 PEAT MANAGEMENT TASK FORCE PEATLAND INFORMATION

Summary of Completed Activities

1.0 PURPOSE

To provide information that will contribute to the orderly development and conservation of peatland ecosystems.

2.0 ASSUMPTIONS

The business plan assumes that:

- a partnership between industry, government and academia will exist;
- a variety of users require peatland information to assess economic and environmental costs and benefits of development and conservation;
- peatland information is an integral part of ecosystem management;
- the ecosystem framework that will be used for peatland description and sampling will be the Natural Regions, Subregions and Ecodistricts of Alberta;
- existing information will be used as much as possible to characterize peatland ecosystems at the provincial scale;
- new information collection is required to identify the location of potential development and conservation opportunities;
- data standards will be defined by the criteria for development and conservation agreed upon by the partners; and
- specified maps and reports will be published and made available to interested users.

3.0 INFORMATION OBJECTIVES

3.1 Peatland Resources of the Natural Regions and Subregions of Alberta

This objective addresses the task of describing what is currently known about peatland types and their distribution in Alberta, within an ecosystem framework. The description will include an assessment of values, opportunities and impacts, with such topics as threatened and endangered plants and animals, hydrologic functions, peat extraction, agriculture, forestry, and oil and gas. In addition, a classification, standard terminology and definitions for the peatland types in Alberta will be documented for use in subsequent inventories.

Results: A report, Peatland Resources of the Natural Regions and Subregions of Alberta.

Tasks: classify and define the peatland types of Alberta peatlands

- interpret air photos and compile peatland data for the project area - forty-two 1:250 000 map sheets
- digitize/scan peatland maps and generate summary statistics
- compile existing information on distribution of peatland values, development opportunities and impacts on the peat resource.
- publish and distribute report

Schedule: • Completed in Year 1 (1996)

Uses: an information source for policy development and implementation

- a provincial overview of the distribution of peatland types and values that provides the context for regional decisions
- a planning tool for Special Places 2000, protected areas management, endangered species management
- shows development opportunities on a regional basis
- supports planning on an ecosystem basis
- an educational tool

3.2 Peatland Inventory

Provides maps and data that classify peatlands and evaluates them for their conservation value and for their potential for horticultural peat extraction. A five year commitment was established to evaluate the 50 000 km² that comprise all the potentially economically important areas of horticultural peatlands in the province. The commitment will allow the inventory program to proceed efficiently by allowing the expertise required to carry out the work to be built and retained.

For the purposes of this inventory, the natural regions, subregions and ecodistricts have been further subdivided to identify areas of more homogeneous peatland types and distribution patterns. These areas are called Peatland Management Areas (PMAs).

Results: For priority Ecodistricts/Peatland Management Areas:

- 1:50 000 black and white maps of peatland types
- 1:50 000 black and white maps of peatlands rated for conservation values and horticultural development potential
- supporting digital files and databases
- report of methods and results

Tasks: tabulate existing information

- interpret air photos
- identify sites and conduct field sampling
- assess development potential
- assess conservation value
- produce maps, databases and reports
- publish and distribute results

Schedule: Year 2: – Wabasca East (Completed in 2000 with assessment of conservation values developed in Forest 2000).

- Year 3: – Athabasca and Wabasca West (Completed in 2002).
- Year 4: – Utikima (Completion Pending)

(Update 2003 - Currently, all of the five years has been essentially completed as shown in Figure A1-1).

- Uses:
- a balanced view of peatland distributions and values
 - allows government to make detailed planning and allocation decisions, and to identify land bases for development and conservation
 - areas of high potential for extraction of horticultural grade peat are identified so that site-specific deposits can be investigated in more detail by the user community
 - areas with high conservation value are identified and, subsequently, further investigation can determine how they can best be managed to preserve their value
 - provides caribou habitat information
 - provides a baseline assessment of the peatland land base prior to development
 - supports ecosystem management
 - provides an opportunity for scientific investigation and the resulting increased understanding of peatlands

3.3 Peatland Information Centre

Provides for safe storage of the inventory results, documents and databases and provides for the generation of products, on a user pay basis.

Results: A Peatland Information Centre

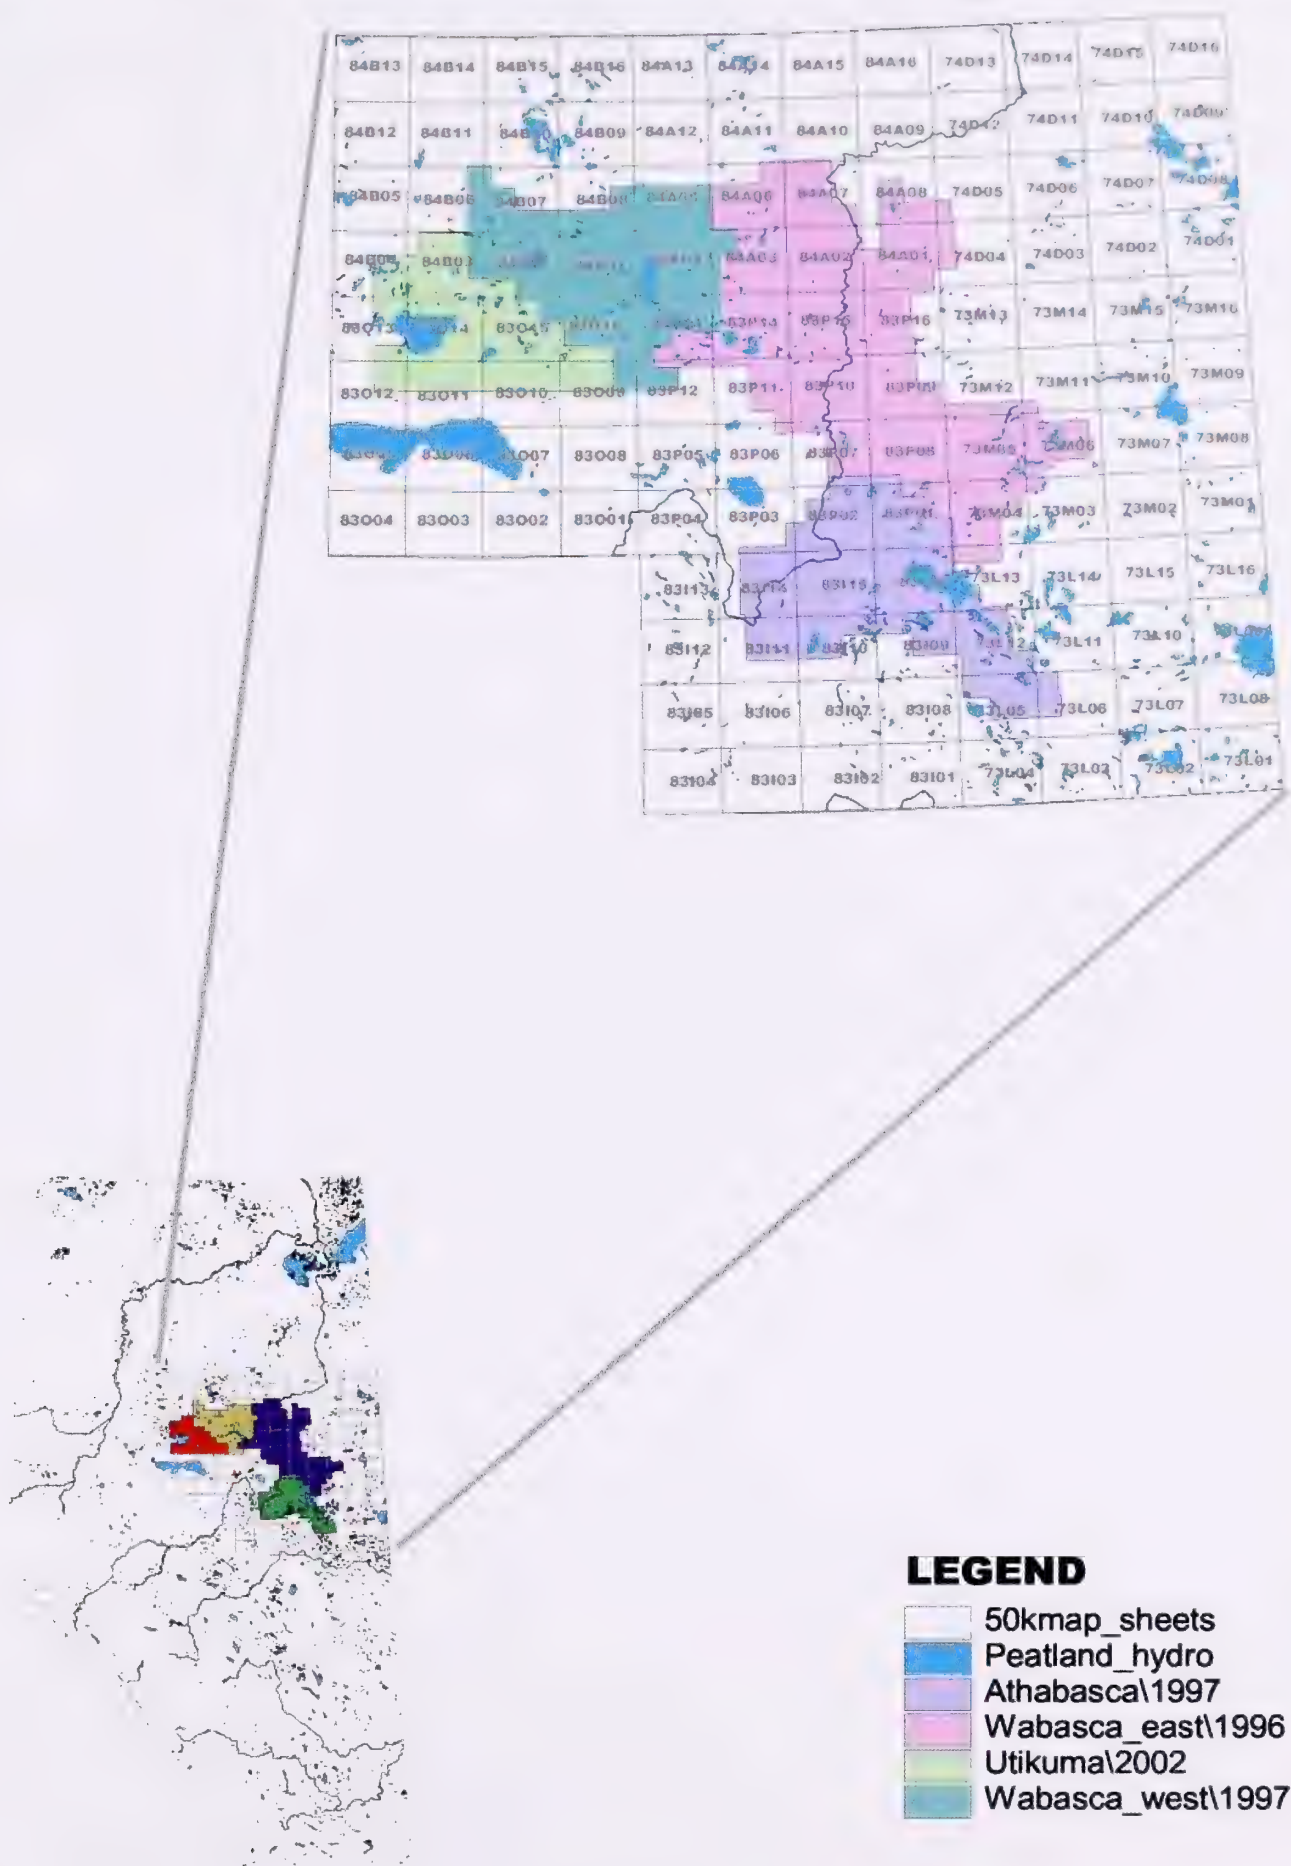

- Tasks:
- design operating strategy for centre
 - organize materials and equipment and load data
 - store and manage the data
 - produce standard and custom products on a user pay basis

Schedule:

- operation initiated at the conclusion of Year 1 at the Devonian Botanic Garden, University of Alberta:
(<http://www.devonian.ualberta.ca/peatland>)

- Uses:
- access to the interpreted air photos for subsequent investigation
 - additional copies of maps and reports for new users
 - access to digital site and map data for user specific modelling
 - production of custom products to identify areas of interest

Figure A1-1: Location of Completed areas for Peatland Inventory.

APPENDIX 2 PEAT MANAGEMENT TASK FORCE PEATLAND SITE INFORMATION

Site layer data collected in Year 3 (1999) by Sonja Mehelcic and David Beilman

APPENDIX 3

PEAT MANAGEMENT TASK FORCE

PEATLAND INFORMATION

Site vegetation data collected in Year 3 (1999) by Sonja Mehelcic and David Beilman.

Layer 1 = Trees > 10m; Layer 2= Tree/shrubs 2 – 10m; Layer 3 = Tree/shrubs 0.5 to 2m; Layer 4 = Tree/shrubs <0.5m.; Layer 5 = Herb; Layer 6 = Graminoid; Layer 7 = Bryophytes; Layer 8 = Lichens; Layer 9 = Aquatic.

Cover values: 0.01 = rare, 1 = uncommon, 2 = common, 3 = ubiquitous

APPENDIX 4

RECOMMENDED CODING FOR ALBERTA WETLAND STANDARDS

INVENTORY

CODING EXPLANATION FOR WETLAND POLYGONS

Refer to Table 4-1 for AWI (AVI) database structure and allowable codes and to Table 4-2 for sample field data recording sheet.

Locational Data – Columns 1 to 19

Column 1 - 10	AWI (AVI) Polygon Number is the unique identification of each polygon; numeric, up to ten digits, e.g. 0000000001 – 9999999999. This unique identifier permits retrieval of locational (ATS) and other information from the AWI (AVI attribute database.
Column 11 – 20	Aerial Photography – Roll Number, e.g. AS4265, GAS4376.
Column 21 - 23	Photo Number, e.g. 167.

Primary, Secondary, Tertiary Wetland Components – Columns 20 - 35

Column 24, 25, 30, 35	Decile: One of two digits from 1 to 10 describing the percentage of the polygon represented by each wetland component. Only the Primary component may have up to two digits (100%). The Secondary component may represent between 20% and 50% of the polygon and may be equal to but not greater than the percentage of the Primary component. The Tertiary component may represent no more that 20% of the polygon. In cases where the proportion of the Primary is 80% and the next component is 20% or more, the Primary and Secondary fields are coded, not the Tertiary fields. Where the next component is 20% or less, the Primary and Tertiary fields are coded. Up to three components are allowed because AVI polygons with “w” or “a” moisture regimes of “F” or “U” timber productivity ratings (TPR) often contain more than one wetland component significant for wetland management.
-------------------------------------	---

Column 26, 31, 36	Wetland Class: Refer also to Table 1 in body of report for definitions and allowable codes. Note that "Z" replaces "MINL" in Vitt et al. 1996 and is used alone for Non-wetland areas.
Column 27, 32, 37	Vegetation Modifier. Refer to Table 4-1 in standards for definitions and allowable codes. The class ranges correspond to groupings in the AVI Crown Closure Classes
Column 28, 33, 38	Wetland Complex Landform Modifier: Refer to Table 1 in standards for definitions and allowable codes.
Column 29, 34, 39	Local Landform Modifier: Refer to Table 1 in standards for definitions and allowable codes.

Other Data – Columns 36 - 70

Column 40	Reliability: Is a character code that indicates the level of confidence in delineating and/or designating the wetland components based on terrain complexity and the mapper's level of expertise. Reliability is coded as H (High), M (Medium), or L (Low).
Column 41	<p>Data Sources: Indicates how the information has been gathered in order to determine wetland polygon units. Data source is coded using a one character code as follows:</p> <p><input type="checkbox"/> Full plots have been recorded for polygon units using the Ecological Site description forms.</p> <p><input type="checkbox"/> Site visit to the polygon unit, either drive or walk through with field notes.</p> <p><input type="checkbox"/> Air observation.</p> <p><input type="checkbox"/> Air photo interpretation.</p>

Appendix 4

TABLE 4-1: Alberta Wetland Inventory – Version 2.0 – Attribute Data Structure

Record Name	No. Byte	Field Type	Field Position	Allowable Codes
AWI (AVI) Polygon Number	10	C	1 to 10	1-9999999999
Aerial Photography – Roll Number	10	C	11 to 20	(AS, WL, etc.) 0001-9999
Aerial Photography – Photo Number	3	C	21 to 23	001 - 9999
WETLAND COMPONENT - PRIMARY				
Decile ($\geq 40\%$)	2	N	24 to 25	4, 5, 6, 7, 8, 9, 10
Wetland Class	1	C	26	B, F, S, M, W, Z
Vegetation Modifier	1	C	27	F, T, O
Wetland Complex Landform Modifier	1	C	28	X, P, N
Local Landform Modifier	1	C	29	C, R, I, N, S, G
WETLAND COMPONENT – SECONDARY				
Decile (20 - 50%)	2	N	30	2, 3, 4, 5
Wetland Class	1	C	31	B, F, S, M, W, Z
Vegetation Modifier	1	C	32	F, T, O
Wetland Complex Landform Modifier	1	C	33	X, P, N
Local Landform Modifier	1	C	34	C, R, I, N, S, G
WETLAND COMPONENT – TERTIARY				
Decile ($\leq 20\%$)	2	N	35	1, 2
Wetland Class	1	C	36	B, F, S, M, W, Z
Vegetation Modifier	1	C	37	F, T, O
Wetland Complex Landform Modifier	1	C	38	X, P, N
Local Landform Modifier	1	C	39	C, R, I, N, S, G
RELIABILITY	1	C	40	H, M, L
DATA SOURCE	1	C	41	E, N, O, P
Interpreter's Initials	2	C	42 to 43	
COMMENTS	21	C	44 to 60	Free format
